***Abstract*—Context switching is a fundamental operating-system primitive whose latency directly governs the responsiveness of concurrent applications on modern multicore processors. Despite decades of research, the interaction between scheduling overhead, workload contention, and hardware microarchitecture remains poorly quantified outside controlled laboratory settings. This paper presents a systematic empirical study of context-switch latency on an Intel Core i5-1035G1 (Ice Lake, 4 cores/8 threads) using the *lmbench* `lat_ctx` microbenchmark. We vary three independent dimensions simultaneously: (i) the number of active CPU cores (1, 2, 4), (ii) the number of concurrently switching processes (2–64), and (iii) the type and intensity of background system load (CPU-bound, I/O-bound, memory-bound, and mixed at 25–100 %). Our results show that memory-bound interference inflates context-switch latency by up to 3.1× over the idle baseline, while restricting scheduling to a single core incurs a further 1.45× overhead. We attribute these effects to LLC eviction pressure, TLB shootdowns, and scheduler run-queue contention, providing a clear microarchitecture-level explanation corroborated by published cache-hierarchy specifications.**

***Index Terms*—context switching, scheduling latency, multicore, lmbench, workload characterization, performance analysis, microarchitecture**

I. Introduction

Modern operating systems achieve concurrent execution by rapidly multiplexing a finite set of processor cores among many runnable threads. Each such *context switch* requires saving and restoring register files, updating the program counter and stack pointer, and — critically — invalidating or warming up micro-architectural state such as branch-predictor histories, Translation Lookaside Buffer (TLB) entries, and cache lines. While the *direct* cost of a switch is on the order of a few microseconds for the kernel bookkeeping alone, the *indirect* cost of re-warming caches can dominate by an order of magnitude, especially when processes hold large working sets [2].

On multicore processors the problem is compounded: the Completely Fair Scheduler (CFS) must balance load across cores, risking process migration that carries an additional cache-migration penalty [3]. Shared last-level caches (LLC) and memory buses mean that a CPU-intensive or memory-intensive co-runner can evict the paused process's cache lines, inflating the next dispatch's warm-up time even without an explicit migration [4].

Contributions. This work makes the following contributions:

- A cross-platform benchmark harness (SSP-Bench) that drives `lmbench lat_ctx` under programmable background workloads with fine-grained intensity control, with a portable Python fallback for Windows environments.
- A three-dimensional scaling study: core count × process count × workload intensity, yielding 5-dimensional result surfaces.
- A microarchitecture-level explanation of observed trends grounded in the Ice Lake cache hierarchy specifications.

Paper organisation. Section III surveys related work. Section II introduces lmbench and context-switch mechanics. Section IV describes the experimental methodology. Section V presents and interprets results. Section VI concludes.

II. Background

A. Context Switching and Scheduling

When the OS preempts a running thread, it (1) saves the architectural state (GPRs, FPRs, SSE/AVX registers, control registers) into the kernel's `task_struct`; (2) selects a new runnable thread via the scheduler policy; (3) restores that thread's state; and (4) performs an `iret` to resume user-mode execution. The "direct" cost is dominated by steps 1 and 3, while the "indirect" cost stems from TLB flushes on address-space switches and cold-start misses in the L1/L2 caches.

CFS, the default Linux scheduler since kernel 2.6.23, computes a *virtual runtime* (`vruntime`) for each task, always selecting the task with the smallest vruntime from a red-black tree. Its scheduling granularity (`sched_latency_ns`, default 6 ms) defines how often a preemption is forced.

B. The lmbench Microbenchmark Suite

`lmbench` [1] is an open-source POSIX microbenchmark suite designed to measure the fundamental cost of OS primitives. `lat_ctx` measures context-switch latency by creating N processes connected in a token ring via pipes. A token is

passed around the ring; the time for K full laps divided by $N \cdot K$ yields the per-switch latency in microseconds. A "-s *size*" flag pre-faults *size* KB of memory in each process to model different working-set sizes, directly simulating cache pressure.

III. Related Work

lmbench (McVoy & Staelin, 1996). The seminal paper introducing lmbench [1] established the token-ring methodology for context-switch measurement and reported latencies of 15–120 μs on 1990s hardware, providing a baseline for comparing subsequent processor generations.

Quantifying Context-Switch Overhead (Li et al., 2007). Li *et al.* [2] decomposed switching cost into direct (kernel bookkeeping: 1.2–1.5 μs) and indirect (cache warm-up: up to 50 μs for large working sets) components, highlighting that LLC capacity is the principal determinant of the indirect cost.

The Linux Scheduler: A Decade of Wasted Cores (Lozi et al., 2016). Lozi *et al.* [3] demonstrated that subtle bugs in the CFS load-balancer resulted in idle cores while runnable threads were queued for busy cores. Their work underscores the importance of empirically validating scheduler behaviour rather than relying solely on code analysis.

NUMA-Aware Contention Management (Blagodurov et al., 2011). Blagodurov *et al.* [4] showed that shared-LLC contention between co-located workloads can reduce IPC by up to 70%, and proposed contention-aware placement policies. Their findings directly motivate our workload-interference experiments.

System-Level Performance Metrics (Eyerman & Eeckhout, 2008). Eyerman and Eeckhout [5] introduced weighted speedup and harmonic mean IPC as metrics for evaluating multiprogrammed workload performance, providing the theoretical grounding for our intensity-vs-latency analysis framework.

IV. Methodology

A. System Under Test

Experiments ran on a laptop equipped with an Intel Core i5-1035G1 processor (Ice Lake, 10 nm, 4 cores / 8 threads, base 1.0 GHz, boost 3.6 GHz). The CPU features 48 KB L1d / 32 KB L1i per core, 512 KB private L2 per core, and a 6 MB shared L3 (LLC). The system runs Ubuntu 22.04 with Linux kernel 6.5. Table I summarises the configuration.

TABLE I
System Configuration

Parameter	Value
CPU	Intel Core i5-1035G1 @ 1.0/3.6 GHz
Microarchitecture	Ice Lake (10 nm)
Cores / Threads	4 / 8
L1d / L1i (per core)	48 KB / 32 KB
L2 (per core)	512 KB
L3 (shared)	6 MB
DRAM	24 GB DDR4-3200
OS / Kernel	Ubuntu 22.04 / Linux 6.5
lmbench version	3.0-a9

B. Benchmark Harness

We developed SSP-Bench, a Python orchestration framework that (a) pins the benchmark process to the first C logical CPUs using `taskset`, (b) launches W background load-generator workers (Python subprocesses), and (c) invokes `lat_ctx -s` D N with D KB context size and N processes. Each configuration is repeated three times; the maximum sample is discarded as an outlier, and the remaining two are averaged. Source code is available in the project repository.

C. Independent Variables

- **Active cores** $C \in \{1, 2, 4\}$: enforced via CPU-affinity mask (`taskset`).
- **Process count** $N \in \{2, 4, 8, 16, 32, 64\}$: fed directly to `lat_ctx`.
- **Context data size** $D \in \{0, 16, 64\}$ KB: models increasing working-set sizes relative to L1/L2 capacity.
- **Workload type**: idle baseline; CPU-bound (arithmetic loop); I/O-bound (repeated 128 KB file write/read/fsync); memory-bound (strided 512 MB array traversal); mixed (CPU + memory).
- **Workload intensity** $I \in \{25, 50, 75, 100\}$ %: duty-cycle fraction for CPU; block size / access rate for I/O and memory.

D. Dependent Variable

The primary metric is **context-switch latency** in microseconds (μs), as output by `lat_ctx`. Secondary metrics include the standard deviation across repetitions (stability measure) and the *slowdown ratio*: $\mathrm{SR} = \mathrm{latency}_{\mathrm{loaded}}/\mathrm{latency}_{\mathrm{baseline}}$.

V. Results and Discussion

A. Baseline Characterisation

Fig. 1 shows context-switch latency as a function of process count for three data sizes (0 KB, 16 KB, 64 KB) with all four cores active. With a 0 KB context the idle-system latency rises from 3.1 μs at N=2 to 5.8 μs at N=64 — a trend driven by increased run-queue contention and CFS re-balancing overhead. Increasing the context to 16 KB raises base latency by $\sim$1.4 μs because the working set now exceeds the 48 KB L1d cache, forcing L2 warm-up after each switch. At 64 KB (exceeding L2), the overhead grows further, plateauing near 9.5 μs at high process counts as LLC misses dominate.

B. Workload Interference

Fig. 2 plots latency versus background workload intensity at N=8 processes and 0 KB context. The idle baseline sits at 3.8 μs. CPU-bound interference raises latency modestly (to 5.8 μs at 100 %), primarily through increased scheduler run-queue depth rather than cache effects. Memory-bound load is substantially more damaging: at 100 % intensity the latency reaches 11.9 μs (SR = 3.1 $\times$) because the strided 512 MB memory accesses continuously evict LLC lines belonging to the benchmarked processes. Mixed load is the worst offender (SR = 3.6 $\times$), combining both CPU-queue pressure and LLC eviction.

Fig. 1. Baseline context-switch latency vs process count for three context data sizes (0, 16, 64 KB) with all 4 cores active. Error bars show ± 1 std over three measurements.

Fig. 2. Context-switch latency vs background workload intensity for CPU-bound, I/O-bound, memory-bound, and mixed loads (N=8 processes, 0 KB context, 4 active cores). Dashed line marks the idle baseline.

C. Core Scaling Effect

Fig. 3 presents a latency heatmap over the (active cores $\times$ process count) space at the idle baseline and 0 KB context. Two trends are evident:

1) **Fewer cores $\Rightarrow$ higher latency.** With only one active core, latency at N=64 reaches 8.4 μs vs 5.8 μs with four cores (a 1.45$\times$ penalty). This is expected: a single core must time-multiplex all 64 processes on a single run queue with no parallelism to hide queuing delay.
2) **Process count saturates beyond N>16.** Latency growth flattens above 16 processes because CFS's sched_latency distributes timeslices uniformly; beyond this point additional token-ring hops add approximately constant queuing time.

Fig. 3. Heatmap of context-switch latency (μs) vs active core count (rows) and process count (columns), baseline workload, 0 KB context. Lower values are better (cooler colour).

D. Comparative Workload View

Fig. 4 groups all workload types by core count. At 4 cores the latency ordering is: Baseline < I/O < CPU < Memory < Mixed, which aligns with the LLC-eviction hypothesis: I/O load mainly stresses the VFS layer and does not dirty LLC lines used by the benchmark; CPU-bound load competes for execution slots without significant cache impact; memory-bound load aggressively evicts LLC lines, stalling post-switch cache warm-up.

Fig. 4. Grouped bar chart of peak-intensity context-switch latency per workload type, broken down by active core count (N=8, 0 KB context). Error bars show ± 1 std.

E. Microarchitecture Interpretation

The observed results map cleanly onto the Ice Lake cache hierarchy:

- **0 KB context (L1-resident):** warm-up after a switch takes $\sim$4 cycles (L1 hit latency); hence direct syscall cost dominates and base latency is 3–4 μs.
- **16 KB context (L1-spilling):** partial data must be fetched from L2 (12-cycle latency); warm-up adds $\sim$1 μs.
- **64 KB context (L2-spilling):** data spills into the 6 MB LLC (42-cycle latency); the additional cost is $\sim$3 μs.
- **Memory-bound load with 512 MB working set:** the LLC is entirely occupied by the load; every post-switch access becomes a DRAM miss ($\sim$70 ns or $\sim$250 cycles

at 3.6 GHz), inflating warm-up to several microseconds per switch.

These figures are consistent with published Intel Ice Lake memory-subsystem characteristics and corroborate the work of Li *et al.* [2].

VI. Conclusion

We presented a systematic three-dimensional scaling study of context-switch latency on a commodity multicore processor, using the lmbench `lat_ctx` microbenchmark and a novel cross-platform orchestration harness. Our key findings are:

1) Context-switch latency increases sub-linearly with process count, saturating near $N{=}16$ due to CFS scheduling granularity.
2) Restricting execution to a single core imposes a $1.45\times$ latency penalty relative to using all four cores, attributed to run-queue serialisation.
3) Memory-bound background workloads cause the most severe interference (up to $3.1\times$ slowdown), dominated by LLC eviction rather than CPU queuing.
4) The latency hierarchy (baseline $<$ I/O $<$ CPU $<$ memory $<$ mixed) directly mirrors the LLC pressure imposed by each workload class.

These findings have practical implications for real-time and latency-sensitive systems: co-locating memory-intensive batch jobs with interactive workloads should be avoided, and hardware prefetcher configurations or LLC partitioning (Intel CAT) should be considered to isolate LLC capacity for latency-critical threads.

Future work will extend this study to heterogeneous (P-core/E-core) processors, investigate the impact of hardware SMT siblings on switching latency, and evaluate scheduler tunables (`sched_latency_ns`, `sched_migration_cost_ns`) as knobs for mitigating the observed interference.
